ALLERGIC REACTIONS AGAINST COVID-19 VACCINES

Abstract
Coronavirus Disease 2019 (COVID-19) affected the whole world in a short time. One of the most influential public health initiatives modern medicine has to offer, the vaccine has become even more important as the COVID-19 pandemic continues to worsen worldwide. Many vaccine trials were launched during the COVID-19 pandemic and these vaccines were widely used around the world, offering realistic hope for ending the pandemic. Allergic reactions to vaccines were reported shortly after their approval. These reactions in general, are rare but they can in some circumstances be serious. Allergy to vaccines can occur because of either the active vaccine component or vaccine ingredients. The spectrum of the reactions may be just a local hypersensitivity reaction or may be as severe as an anaphylaxis which is an acute severe, life-threatening systemic hypersensitive reaction and it requires quick intervention. If an allergy is suspected, a correct examination followed by algorithms is important for true diagnosis, treatment and decision regarding re-vaccination. Patients who experience an allergic reaction with the first dose of covid 19 vaccine should be directed to the allergy-immunologist and the evaluation of at-risk patients should be individualized. Finally, we should point out that the benefits of current COVID-19 vaccines go far beyond the side effects, and that the vaccine is the most important way to recover from the pandemic.

Keywords: COVID-19, vaccine, allergy, hypersensitivity, polyethylene glycol
1. Introduction

Routine immunization, has effectively reduced death and morbidity rates because of a variety of infectious diseases and it is one of the most effective public health interventions.[1, 2] Severe allergic reactions to vaccines are rare and difficult to predict. In general, anaphylactic reactions to vaccinations are occurring at a rate of about 1 per million.[3, 4] Vaccination has become increasingly important as the global pandemic the 2019 coronavirus disease (COVID-19) continues to worsen worldwide. After the COVID-19 pandemic, many vaccine studies began worldwide and vaccines such as Pfizer/BioNTech BNT162B2, Moderna mRNA-1273 and AstraZeneca recombinant ChAdOx1-S were first approved. Although rare, severe allergic reactions to mRNA-based vaccines were reported shortly after their approval.[4] In this review, we aimed to make an allergic reaction risk assessment related to COVID-19 vaccination and recommend a standard diagnostic and management procedure in case of reaction.

2. Covid-19 Vaccines And Allergic Reactions

RNA vaccines, inactivated vaccines, replication-incompetent vector vaccines and recombinant protein vaccines are different vaccine approaches produced for protection from covid 19 infection. BNT162b2 (Pfizer-BioNTech) and mRNA-1273 (Moderna) are mRNA vaccines and they are delivered in a lipid nanoparticle to express a full-length spike protein. Since the approval of mRNA-based vaccines, severe general reactions have been reported from the United Kingdom and the United States. 21 adverse events detected as anaphylaxis after administration of a reported 1,893,360 first doses of the Pfizer-BioNTech COVID-19 vaccine (11.1 cases per million doses)[5, 6] Anaphylaxis has also been reported from the Moderna mRNA COVID-19 vaccine.[7] This has triggered the need to provide recommendations on how to manage covid 19 vaccine allergic reactions.
The AstraZeneca ChAdOx1-S (Vaxzevria) vaccine, which is a recombinant chimpanzee adenoviral vector, and the Johnson & Johnson Ad26.COV2.S (Janssen) vaccine, which is a recombinant adenovirus type 26 vector, were other produced vaccines on the market.[8, 9]

Approximately 6.85 million doses of Johnson & Johnson COVID-19 vaccine (Janssen) have been administered in the USA. Six cases of cerebral venous sinus thrombosis with thrombocytopenia have been reported after receiving Janssen COVID-19 vaccine. All of the cases consisted of women between the ages of 18-48 and the events occurred 6-13 days after vaccination. One patient has died. In the statement made by the FDA and the Centers for Disease Control and Prevention (CDC), it was recommended to stop the use of Janssen COVID-19 vaccine and the USA, South Africa and the European Union decided to temporarily stop the use.[10]

Unusual cases of thrombotic complications along with thrombocytopenia have been observed in patients after vaccination with AstraZeneca ChAdOx1-S (Vaxzevria). The majority of these reported cases occurred within 2 weeks after vaccination and consisted of women under 60 years of age. The safety committee of EMA (Pharmacovigilance Risk Assessment Committee, PRAC) has comprehensively reviewed 62 cases of cerebral venous sinus thrombosis and 24 cases of splanchnic vein thrombosis, 18 of which were fatal. The EMA declared that, based on the currently available evidence, certain risk factors cannot be confirmed, unusual thrombotic complications with low platelets should be listed as very rare side effects of Vaxzevria, and concluded that the benefits of the vaccine continue to outweigh the risks for those receiving the vaccine.[11] The British Medicines and Healthcare Products Regulatory Agency (MHRA) stated that the benefits of vaccination for people aged 30 and over and those with other health problems outweigh the risk of coagulation problems and for people under the age of 30 who do not have other health problems, it is currently recommended that another COVID-19 vaccine be preferred over the AstraZeneca vaccine.[12]
3. Mechanisms of Hypersensitivity Reactions for Vaccines

An allergic reaction is defined as a harmful idiosyncratic response given by an immune mechanism.[13] Allergic reactions caused by vaccines are usually of Type I and IV hypersensitivity reactions. Immunologically mediated allergic reactions are either acute in onset or delayed.[14] The majority of acute-onset reactions are type I hypersensitivity reactions.[15] Immediate reactions to vaccines is caused by the presence of IgE in a patient which can precipitate degranulation of mast cells (MC) and release of histamine in reply to an antigen within the vaccine.[16]

Mast cells are thought to play a major role in the development of immediate allergic reactions and, as upon activation they release a kind of mediators from stored granules. Also mast cells are involved in homeostasis, inflammation, innate and adaptive immunity, angiogenesis in various tissues.[17] Therefore, they are often found at the host-environment interface, like the skin, gastrointestinal tract or lungs which are threatened by various external factors, pathogens and allergens. Main receptor systems and ligands involved in mast cell activation are shown in Figure 1.[18] Post-activation MCs release numerous mediators in immediate reaction. Histamine, proteases, heparin and prostaglandin D2, leukotriene C4, thromboxane, tumor necrosis factor alpha etc. are among these mediators.[19]

4. Clinical Manifestations

4.1. Immediate allergic reactions

Immediate hypersensitivity to vaccines are rare however, it is important for the clinician to recognize these reactions correctly for the future vaccine administration decision. It has been stated that the average rate for immediate type reactions in children and adolescents is 0.22 per 100,000 doses of vaccinations.[20] Allergic hipersensitivite reactions to vaccines may be mild and limited in the scope of symptoms and involvement of organ systems. The most common
symptoms of IgE-mediated allergic reactions are urticaria and angioedema, with less common symptoms including nasal congestion, wheezing, cough, stridor, vomiting, diarrhea abdominal pain and hypotension. Thus, typical signs of an allergic reaction occurring an onset within minutes and less than 4 h post-vaccination.[21-23]

4.2. Anaphylaxis

Anaphylaxis is an acute severe, life-threatening generalized or systemic hypersensitive reaction.[24-26] Anaphylaxis is triggered by the binding of an allergen to specific immunoglobulin E (IgE). Anaphylaxis to vaccines are rare. The incidence of anaphylaxis with vaccine estimated at 1.31 in 1 million doses given.[3] Anaphylaxis is a rapidly progressive allergic reaction involving multiple organ systems such as skin, respiratory, circulatory and gastrointestinal systems. Although skin findings are the most common, skin findings may not be seen in anaphylaxis.[27-29] Symptoms of anaphylaxis generally have their onset within minutes and symptoms usually start within the first hour after immunization.[22] The faster the anaphylaxis begins, the more severe the reaction. Although uniphasic reactions are mostly seen, 20% biphasic reaction can be seen.[30] Vaso vagal reactions may occur after vaccination and can be confused with anaphylaxis.[31] Bradycardia, vasodilatation and hypotension occur and pallor, nausea, vomiting, profuse sweating, myoclonus and/or incontinence such symptoms can be seen. Hypotension may occur in both vasovagal reactions and anaphylaxis. Absence of bronchospasm and particularly cutaneous manifestations in vasovagal reactions is important in differential diagnosis. Heart rate usually high in anaphylaxis but bradycardia is always seen in vasovagal reactions.[30, 32] In the patient group with a history of vasovagal reaction, future vaccines should be administered while lying supine.[31]

4.3. Delayed reactions
Delayed type reactions can be seen generally days after exposure, but the onset of symptoms can be as early as 6 hours or delayed for up to 2 to 3 weeks. These reactions may be non-immunologic or immunologic. Maculopapular rash on the skin is the most common symptom of delayed-type reactions.[16, 33] Aluminum containing vaccines may cause an injection site nodule, this may be involved to delayed type hypersensitivity to aluminum.[34]

4.4. Local reactions

Local reactions include pain, redness, and/or swelling at injection site are common and self-limited. Large local reactions are less common and generally occur within 24-72 hours after administration.[35] Mild local reactions are seen due to nonspecific inflammation both from the vaccine injection itself and from the injection of foreign substances. Therefore the administration technique is important. Deeper injection application and injection in the thigh rather than the arm are associated with a lower incidence of local reactions.[35-37] Local reactions and constitutional symptoms, especially fever, are common after the administration of many vaccines and that do not contraindicate administration of future doses of the same vaccine.[38, 39]

5. What are the possible causes of Covid 19 vaccine reactions?

Vaccines include not only the antigen in charge of stimulating the immune response but they also contain a number of additional ingredients. Therefore, an allergic reaction occurs not only against the active ingredient itself but also against the vaccine components. Covid 19 vaccines and their ingredients are shown in the Table 1.[40]. To date, allergic reactions mostly related to covid-19 vaccines have been attributed to two important ingredients, polyethylene glycol and polysorbate 80.

5.1. Polyethylene glycol (PEG)
Allergic reactions to vaccines are often due to additives, preservatives and other ingredients rather than the active ingredient itself.[15, 40] Pfizer-BioNTech and Moderna Covid-19 mRNA vaccines are not formulated with any drugs, food or latex. Both vaccines contains, in addition to the modified viral mRNA, various salts, carbohydrates and lipids and the excipient PEG (Polyethylene glycol). [41, 42] At present, there are no other vaccines that use PEG 2000. PEG, also known as macrogol, is an excipient for the purpose of stabilizing the lipid nanoparticle containing the mRNA. PEG is widely used in many daily products including; cosmetics, drugs, lozenges, laxatives, food additives and rarely trigger hypersensitiv allergic reactions.[43-49]

IgE-mediated hypersensitiv reactions and anaphylaxis have been reported to PEGs of different molecular weights and the majority of reactions are due to high molecular weight PEGs.[45, 47] Otherwise, PEG can trigger non-IgE dependent complement mediated mast cell activation through IgG or IgM. This situation is called “Complement Activation-Related Pseudoallergy” (CARPA) which is caused by the activation of the complement system. These hypersensitivity reactions occur directly upon first exposure to lipid excipients, including lipid nanoparticles without prior sensitization, and the symptoms generally decrease or disappear on subsequent treatment. Thus, such immunological responses are called ‘pseudoallergy’. [42, 50, 51]

5.2. Polysorbate 80

The AstraZeneca recombinant adenoviral ChAdOx1-S vaccine contain the excipient polysorbate 80. Polysorbate 80, also known as Tween 80. Polysorbate, structurally similar to PEG. Polysorbate is also an excipient in a many medical products (eg, vaccines, vitamin oils, anticancer agents), ointments, lotions, creams, and medication tablets.[41, 52] At least 70% of injectable biological agents and mAb treatments include a polysorbate. Most typically there is polysorbate 80.[53] Polysorbate 80 has been used as excipient in numerous vaccines (eg influenza vaccines, pneumococcal conjugate vaccine, DTaP and its analogs, HepB, HPV,
zoster). [40] Polysorbate can crossreact with PEG and may cause IgE-mediated hypersensitivity reactions.[54]

5.3. Patient Related risks and Covid-19 Vaccine Allergy

A history of food, venom, inhalant, latex, pet allergies and allergy to oral medications (including the oral equivalent of an injectable medication) are particularly listed as not being precautions or contraindications for receiving the covid 19 vaccine. In case of mastocytosis/mast cell activation syndromes, idiopathic anaphylaxis, severe or multiple drug allergy and previous anaphylaxis to other vaccines, patients should be referred to an allergist before vaccination but these are not considered contraindications. These patients are considered to be observed for 30 minutes after vaccination and vaccination in a hospital setting is recommended. (Table 2)[40, 55] These vaccines are contraindicated in case of allergy to one of the components of the vaccine and in case of severe allergic reaction to the first dose. [40, 55, 56] Although no severe reaction to vaccines have been noticed, a strong relationship has been observed between anaphylaxis and asthma, particularly when asthma is not well-controlled.[57] If there is uncontrolled asthma, vaccination is recommended in a hospital setting. If patients are allergic to latex, vaccination is done only with latex-free gloves.[56] Patients with only a delayed onset local reaction around the injection site after the first vaccine dose, do not have a contraindication or precaution to the future dose. [55, 58, 59]

6. Management of severe hypersensitivity reactions and anaphylaxis

Anaphylaxis is considered a medical emergency with its immediate onset and rapid progression to cardiovascular and/or respiratory collapse resulting in death within minutes of inception. Therefore, it requires quick intervention. The first thing to do is to quickly evaluate the patient's circulation, respiration, consciousness and skin findings and to give the appropriate position. Adrenaline should be administered immediately in patients with a diagnosis of anaphylaxis or
with a high probability. It should be known that delayed adrenaline therapy may cause the reaction to progress rapidly and result in death. Adrenaline administered intramuscularly (in a dose of 0.01 mg/kg of a 1:1000 [1 mg/mL] solution to a maximum of 0.5 mg in adults and 0.3 mg in children). Adrenaline should be administered intramuscularly (IM) to the middle anterolateral part of the thigh (vastus lateralis muscle).[26, 27, 60] Depending on the clinical condition of the patient, the dose can be repeated every 5-15 minutes. The patient should lie on her/his back and legs up. The patient's blood pressure, heart rate, O2 saturation should be measured periodically, and respiratory and cardiac status should be evaluated.

If hypotension persists or signs of cardiovascular shock occur despite IM given adrenaline, rapid IV fluid (saline) replacement is required. Crystalloids are the fluid of choice and should be given in boluses of 20 ml/kg. [24, 61] Patients with respiratory distress should be given high flow oxygen (preferably 100% using a non-rebreather facemask).[62] In the presence of shortness of breath and wheezing despite the injection of adrenaline, inhaled beta 2 agonists can be applied.[24, 63] Antihistamines are effective on skin, nasal and eye symptoms. However, they do not prevent the development of airway obstruction, hypotension and shock. Therefore, they should not replace adrenaline.[64] The role of corticosteroids in the treatment of anaphylaxis is controversial. However, it has not been shown that corticosteroids reduce the severity of the reaction or prevent premature death in anaphylaxis. It should never be administered before adrenaline and it should be known that it will not replace adrenaline in anaphylaxis.[64-66] Glucagon should be administered in cases where anaphylaxis develops while using beta blockers, if hypotension persists despite adrenaline administration. 1-5mg in adults and 20-30 μg/kg (maximum 1mg) in children should be IV administered over 5 minutes. Then 5-15 μg/dk IV infusion is continued.[24, 67] The algorithm of diagnosis and treatment for covid 19 vaccines related reactions is shown in figure 2.[24, 56]
All patients with anaphylaxis should be observed until symptoms have completely resolved. Patients who presented with respiratory failure should be with care monitored for at least 6–8 hour, and patients who presented with hypotension require monitoring for at least 12–24 hour.[24] Patients with a severe initial presentation or the need for more than one dose of epinephrine may be at increased risk for recurrent symptoms so an extended observation period of 24 hours is recommended for patients.[56, 60] In the case of a severe anaphylactic reaction, the risk of biphasic anaphylaxis increases. Risk factors for the occurrence of biphasic anaphylaxis can be summarized as needing repeated doses of epinephrine (ie >1 dose of epinephrine), unknown trigger of anaphylaxis, large pulse pressure, drug-induced anaphylaxis in children, and cutaneous signs and symptoms.[60] On discharge, patients should be instructed to see an allergist immunologist for the future vaccination decision.

7. Follow up and Diagnostic Procedures

7.1. The management of patients who experience potentially allergic reactions to a COVID-19 vaccine

Patients who experience an allergic reaction with the first dose of covid 19 vaccine should be directed to the allergy-immunologist for the next dose of vaccine approach. The evaluation of at-risk patients should be individualized. Patients with a previous history of anaphylaxis against a vaccine should be revaccinated only if absolutely necessary.[35] A split-dose challenges protocol could provide an option for administration in case of at higher risk for developing serious or fatal COVID-19 infections and who have already experienced a suspected or confirmed severe allergic reaction to a COVID-19 vaccine or any of its components. For other vaccines split-dose challenges (administer 0.05 mL of 1:10 dilution, and 10%, 20%, 30%, and 40% of the full dose incrementally in alternate arms at 15-minute intervals, followed by a
minimum 30-minute observation period) have been used.[5, 22] That it is typically performed
with other vaccines but at present, there are no supportive efficacy or safety data for this
approach.

As a different approach; patients with negative skin tests to the vaccine however with a history
of anaphylaxis or severe allergic reactions can be immunized with split-dose vaccination. At
first, 10% of the dose is administred, followed 30 min later by the remaining 90% provided that
no allergic reaction has occurred following the initial dose. These vaccination approaches
should only be used by experienced personnel in a controlled settings where emergency
treatment of anaphylaxis is available [35].

Patients who have experienced a systemic allergic reaction to vaccine should not receive a
second dose of that vaccine, nor a vaccine with similar ingredients. European Medicines
Agency (EMA) and U.S. Food and Drug Administration (FDA) recommended the vaccine
should not be administered if there is an allergy to one of the components of the vaccine and if
there was a severe allergic reaction to the first dose. Vaccination should be administered under
close medical supervision with appropriate medical attention. [56, 68] For people who have a
contraindication to one type of COVID-19 vaccine that is currently permitted, care should be
taken to apply other vaccines. Such as patients with a contraindication to one of the mRNA
Covid-19 vaccines should not receive doses of either of the mRNA vaccines. Both mRNA
Covid-19 vaccines contain Polyethylene glycol (PEG) and the AstraZeneca-ChAdOx1-S
Covid-19 vaccine contain polysorbate 80. Cross-reactive hypersensitivity may occur between
PEG and polysorbate but after appropriate precautions have been taken, in case of with a
contraindication to mRNA COVID-19 vaccines may be able to receive Janssen COVID-19
vaccine, and vice versa.[55] If not otherwise contraindicated (for example; a proven allergy to
polysorbate 80), UK recommendation is that the AstraZeneca vaccine can be used as an
alternative.[40].
7.2. Diagnostic procedures

Allergological study include; detailed history and in vitro tests with the vaccines and their components. The sensitivity and specificity of skin tests with vaccines in confirming or discarding allergy to a vaccine or its ingredients have not been established.[13] But, if skin testing results negative, it is very unlikely for the patient to have IgE against the vaccine or its ingredients. If the suspected vaccine contains specific components, known to be potentially allergenic, testing should also be conducted for those components. A prick test can be performed with the culprit vaccine solution as well as with PEG and polysorbate (titrated 10% and 1%). Currently the limited covid 19 vaccine supply, lack of information about sensitivity or specificity, and uncertain safety of the skin testing; these can interfere with skin testing with the vaccine.

PEG and polysorbate skin testing may be of value in decision making around future COVID-19 vaccination. PEG 3350 is available as a laxative (miralax and others) for prick skin testing and Refresh Optive Advanced Lubricant eye drops and Prevnar are an alternate source for polysorbate 80 skin testing.[41] Concentrations as high as 100 percent (17 g/17 mL) have stated to be nonirritating for prick skin testing.[45, 47] If the PEG prick skin test result is negative, an intradermal test can be performed, at first a 1:100 dilution and if negative at a 1:10 dilution.

It is still unknown whether a negative prick test has sufficient positive or negative predictive power to determine the risk of a serious systemic reaction. Systemic reactions, including anaphylaxis, have been associated with both skin prick testing and intradermal testing.[41, 69] So these tests should be performed with evaluating the benefits and risks by experts in an appropriate settings.
8. Conclusion

Covid 19 virus has killed millions worldwide, however only a very small number of patients have suffered from reactions after vaccination. It is very important that patients understand the overall benefit of vaccination against SARS-CoV-2 and they should be aware that an extremely low overall risk of allergic reactions is related. As allergists, we must be clear and evidence-based about allergic reactions risk with these vaccines. In near future molecular diagnostic methods may also be used and desensitisation protocols with vaccine or vaccine components can be applicable. The most important thing to keep in mind is that the benefits of the vaccine go far beyond the side effects, and most vaccine-related side effects are mild allergic reactions.

**Figure 1:** The structure of the mast cell: Main receptor systems and ligands. [18]

- **Administration of the covid 19 vaccine**
  - Observation for 15 minutes after vaccination [prolonged observation (30 minute) time if patients are at high risk]
  - Only urticaria or Angioedema
    - Antihistamine and glucocorticoids (P.O./L.V.)
    - Observe for 4 hours
    - Consider administering I.M. adrenaline if additional symptoms develop
  - Sudden Onset of Symptoms in 2 or More Organs or Hypotension, Laryngeal Edema, Cardiovascular Collapse
    - Lie patient on back with legs raised (unless respiratory distress)
  - I.M. ADRENALINE
    - I.M. adrenaline dose 0.01mg/kg (1mg/ml)
    - OR
    - 7.5 to 25kg: 0.15mg adrenaline auto-injector and >25kg: 0.3mg adrenaline auto-injector
    - If bronchosospasm: High flow oxygen, beta-2 agonist (4-10 puff) inhaler
    - If hypotension: High flow oxygen, normal saline (20ml/kg I.V. or intraosseous)
  - If resolved whole symptons: respiratory symptoms or signs should be observed for at least 6 to 8 hours, hypotension or collapse observed at least 12-24 hours
  - Repeat I.M. adrenaline in 5-10 minute if no clinical improvement
  - If symptoms continues:
    - Repeat I.M. Adrenaline
    - I.V. adrenaline consider
    - Receive intensive care support
  - Refer to allergy clinic
